Abstract:　This paper proposes a novel work mode of spaceborne ScanSAR with multiple azimuth beams, where the range swath coverage can be greatly extended while the azimuth high resolution remains unchanged. Based on the analysis of the characteristics and main phase errors of this mode, the compensating methods for these errors are given. Then the echo data simulating methods for this mode are introduced and the corresponding imaging algorithms are discussed as well. Thus the feasibility of this mode and the validity of the compensating methods are proved by simulation.

1　INTRODUCTION

ScanSAR is a wide-swath spaceborne SAR mode. But the performance of wide swath is at the expense of the greatly declined azimuth resolution (Andrea *et al.*, 1996; Eldhuset *et al.*,1995; Jurgen *et al.*,2002). The technique of displaced phase centers multiple azimuth beams (DPCMAB) can improve the azimuth resolution greatly on the premise of maintaining a low pulse repetition frequency (PRF) (Currie *et al.*,1992; Gerhard *et al.*, 2004; Kou *et al.*, 2009). If we combine these two modes, the performance which can not be obtained by single mode is achieved. Based on this idea, a new mode (MAB- ScanSAR) is proposed which adopts six azimuth beams and five elevation subswaths. The overall swath width is extended five times while the same azimuth resolution as conventional stripmap SAR is remained. Firstly, the principle and main phase errors of MAB-ScanSAR are analyzed and the corresponding compensating equations are deduced. Secondly, the raw data simulation methods under different conditions are presented and several imaging algorithms fit for MAB-ScanSAR are discussed too. Lastly, the effectiveness of this mode is proved by simulation.

2　BASIC PRINCIPLE OF MAB-SCANSAR

2.1　Principle of DPCMAB

The essential idea of DPCMAB is to substitute high sampling frequency in space domain for high sampling frequency in time domain. Hence, a higher effective azimuth sampling rate can be obtained for a certain system operating PRF. The system operating PRF is the actual pulse transmitting frequency in SAR system and corresponding to it is the equivalent PRF. If there are *N* receivers in azimuth direction, then *N* echoes can be received for every transmitted pulse. From the view of the receiver, the PRF is improved *N* times and the improved PRF is called equivalent PRF.

Fig. 1 illustrates the antenna principle of six azimuth beams SAR. The transmitter (S) is at the middle of the antenna and the receivers are at its two sides. Assuming the overall antenna length is *L*, the distances of transmitter to respective receivers are displayed in Fig.1. The left side receivers are denoted by negative sign in the figure. The azimuth aperture is extended six times by the weighted antenna (Doppler bandwidth is broadened six times) when the system works. Meanwhile, the equivalent PRF is improved six times by the six receivers, but the system operating PRF is still kept unchanged. In the end,

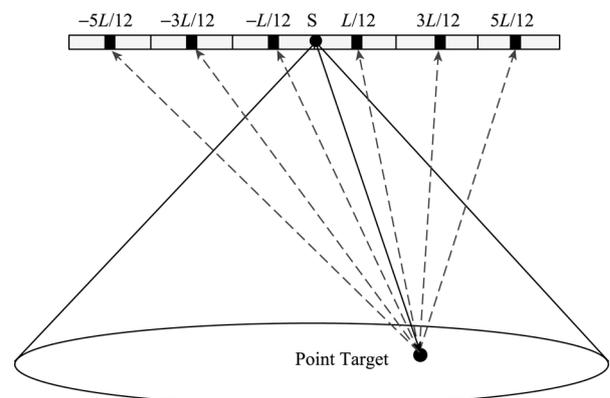

Fig. 1　Antenna principle of six azimuth beams SAR

the azimuth resolution is improved six times than the conventional stripmap SAR.

2.2　Principle of ScanSAR

Fig. 2 displays the principle of a single-look ScanSAR with five subswaths. T_{Dj} is the dwell time of subswath j and it determines the real azimuth resolution. T_R is the signal cycle and it is defined as the time interval between the beginnings of two adjacent bursts at a given subswath.

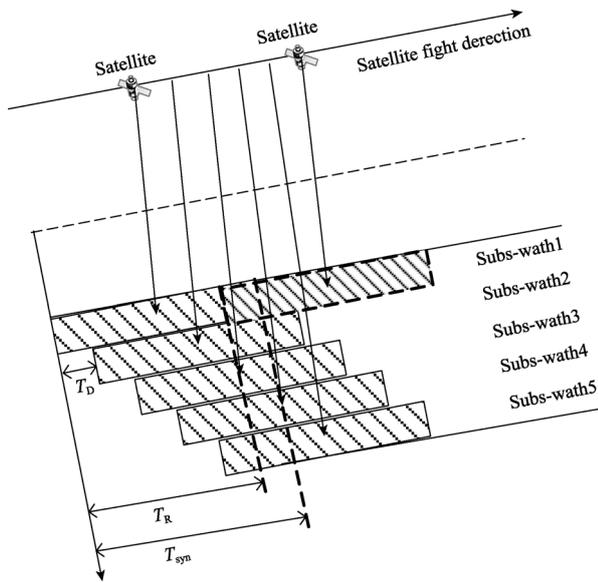

Fig. 2　Principle of five subswaths ScanSAR

Assume T_{syn} expresses the synthetic aperture time of every subswath, to achieve continuous along-track image, the preceding times should satisfy

$$T_{syn} \geqslant T_R + T_{Dj} \qquad j = 1,...,N_B \qquad (1)$$

where N_B is total number of subswaths and T_R meets Eq.(2).

$$T_R = \sum_{j=1}^{N_B} (T_{Dj} + T_c) \qquad (2)$$

where T_c is the beam switching time between subswaths. Assume the dwell times are equal and T_c is neglected ($T_D \gg T_c$), Eq. (1) can be rewritten as follows.

$$T_{syn} \geqslant (N_B + 1)T_D \qquad (3)$$

Since azimuth resolution ρ_{burst} is determined by real bandwidth $f_{dr} \cdot T_D$, based on the preceding relations we can obtain the following equation.

$$\rho_{burst} = \frac{v_g}{f_{dr} \times T_D} \geqslant \frac{v_g(N_B+1)}{f_{dr} \times T_{syn}} = (N_B+1)\rho_{strip} \qquad (4)$$

where f_{dr} is Doppler rate, v_g is the velocity of beam footprint, and ρ_{strip} is the azimuth resolution of conventional stripmap SAR. Eq.(4) shows that the azimuth resolution in the ScanSAR which has N_B subswaths will be degraded at least N_B+1 times than the corresponding stripmap SAR. But if we ignore the overlap between the subswaths, the overall swath width is extended N_B times.

2.3　Principle of MAB-ScanSAR

If five elevation subswaths are adopted in the six azimuth beams SAR, then MAB-ScanSAR proposed in the paper is achieved. The azimuth resolution is improved six times on the premise of maintaining the operating PRF unchanged by six azimuth beams. Meanwhile, the azimuth resolution is degraded six times because of the five subswaths (the resolution is equal to conventional stripmap SAR again) while the overall swath width is extended five times now.

Generalizing MAB-ScanSAR further, the relations of azimuth receivers number N_R, elevation subswaths number N_B, and performance of the system can be described as following: the swath width can be extended N_B times regardless of the value of N_R. However, the azimuth resolution will vary with the value of N_R. If $N_R = N_B + 1$, the same azimuth resolution as stripmap SAR is obtained. If $N_R > N_B + 1$, a better azimuth reso-lution than conventional stripmap SAR is achieved. If $N_R < N_B + 1$, the resolution is degraded. The choices of N_R and N_B can be determined by the preceding relations during system design. In spite of different scenarios, the analysis of phase errors is same to the instance discussed in the paper.

3　PHASE ERRERS AND COMPENSATIONS IN MAB-SCANSAR

The process methods of conventional ScanSAR can be used directly in MAB-ScanSAR, if the phase errors due to multiple azimuth beams are corrected.

3.1　Analysis of the phase errors caused by six azimuth beams

Main phase errors due to multiple azimuth beams are differential path error (Kou *et al.*, 2009) and nonuniform sampling error (Currie *et al.*, 1992). Differential path error is caused by the Earth rotation. This error occurs between the real signal propagation path and the equivalent signal propagation path. It has significant effect on the imaging quality in high frequency SAR.

Fig. 3 displays the relative positions of the antenna and the ground target at a certain moment in the six azimuth beams SAR. S_0 is the transmitter phase center, E_i are effective phase centers, R_i are receiver phase centers, P_0 is ground point target's position at current time, A_i are equivalent ground target's position on the rotational Earth when the equivalent single channel SAR locates at E_i, and $i = -3, -2, -1, 1, 2, 3$ (negative sign denotes left side). The six received echoes in six azimuth beams SAR will be used to mimic six receiving operations of the single beam SAR at the corresponding effective phase center E_i. The movements of antenna and ground point target at each transmitting-receiving are continuous in single beam SAR. However, the phase histories are discontinuous and six echoes are set as one group in six beams SAR. The difference of these phase histories is the basic cause of differential path error. This phase error is generated by the difference between $|S_0P_0R_i|$ and
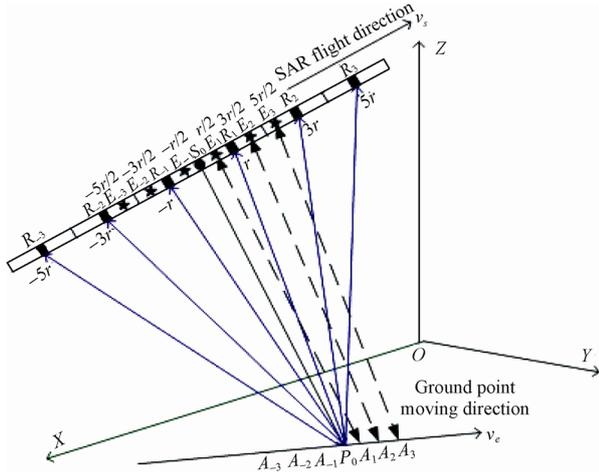

Fig. 3   Differential path error in six azimuth beams SAR

$2|E_iA_i|$ in Fig. 3. They can be approximated by $2|E_iP_0|-2|E_iA_i|$, as the difference between $2|E_iP_0|$ and $|S_0P_0R_i|$ can be ignored at all (Currie *et al.*, 1992). To keep the figure clear, only right side equivalent propagation paths are plotted in Fig. 3. The distances of the transmitter to the receivers and the effective phase centers are marked on the figure, where r is half length of the equivalent antenna. If the overall antenna length is L, the equivalent antenna length in six beams SAR is $L/6$ m. As a result $r = L/12$ m.

The nonuniform sampling error means the azimuth nonuniform which the antenna moving distance does not equal to $L/2$ within an interval of pulse repetition. In Fig. 3, this error occurs when the distance between the leftmost effective phase center E_{-3} at next moment and the rightmost effective phase center E_3 at current time does not equal to r. The phase history of multiple beams can be expressed as follows.

$$\phi_a(n) = -4\pi / \lambda R(n\text{PRI}/6) + \phi_W(n) + \phi_u(n) =$$
$$-4\pi / \lambda R(n\text{PRI}_e) + \phi_W(n) + \phi_u(n) \qquad (5)$$

where $n=0, 1, 2, 1\ldots$ is azimuth pulse number in the equivalent single beam SAR, PRI is system operating pulse repetition interval, PRI_e is equivalent pulse repetition interval, $\phi_W(n)$ is differential path error, and $\phi_u(n)$ is nonuniform sampling error. Based on the geometry of the satellite and the Earth, $\phi_W(n)$ can be expressed as follows.

$$\phi_W(n) \approx \{[2\bmod(n,6) - 5]L\pi\omega_e \times$$
$$R_e \cos\Phi_t \cos\delta\}/(6\lambda v_s) \qquad (6)$$

where $\bmod(n,6)=0,\ldots, 5$ denotes the beam number starting from left side, ω_e is the Earth rotation velocity, R_e is radius of the Earth, Φ_t is latitude of the ground point target, λ is wavelength of radar carrier, v_s is satellite velocity, δ is the angle between radar beam and ground target velocity.

$$\cos\delta = (R_s / R_{st})\sqrt{\cos(\Phi_s + \Phi_t) + \cos\alpha} \times$$
$$\sqrt{\cos(\Phi_s - \Phi_t) - \cos\alpha} / \cos\Phi_t \qquad (7)$$

where R_s is radius of the satellite orbit, R_{st} is the distance between the satellite and the ground point target, Φ_s is latitude of nadir, and α is Earth centre angle (between spacecraft radius vector and scatter location vector).

Azimuth nonuniform sampling error can be compensated by spectrum reconstruction (Kou *et al.*, 2009; Yin, 1997) etc. Certainly, the analytic expression of $\phi_u(n)$ can be written out based on the specific orbit and Earth model and compensated as a phase error. However, the radar satellites nowadays almost all have yaw steering which reduces the effect of nonuniform sampling error significantly. The simulation analysis of the preceding errors is presented in section 6.

3.2   Problems due to scan in elevation

In MAB-ScanSAR, problems due to scan in elevation direction are the same as the conventional ScanSAR. They are the stitching of image blocks inside or outside the subswath, variation of ground resolution in range direction etc.

4   ECHO DATA SIMULATION IN MAB-SCANSAR

A local sphere Earth and circle orbit model is adopted. The geometry relationships are represented by eight coordinates and echo data under different conditions can be generated by the following methods.

4.1   Simulation of yaw steering

Yaw steering is a technique which can maintain the Doppler centric frequency f_{dc} at zero all the time. It is realized by adjusting the yaw angle along the orbit continuously. In simulation, the yaw angles at different orbit positions can be calculated by Eq.(8) (Raney, 1986).

$$\tan a = \varepsilon(\omega_s / \omega_e - \cos\psi)/(\cos\beta\sin\psi) \qquad (8)$$

where a is yaw angle, β is satellite latitude, $\varepsilon=1(-1)$ denotes radar works in left & right side looking mode, ψ is the orbit inclination angle, ω_s is the satellite orbital rotation rate, and ω_e is the Earth rotation rate.

4.2   Simulation of multiple azimuth beams

The simulation of six azimuth beams in Fig.3 can be distinguished into following three categories: (1) only differ- rential path error is considered; (2) only nonuniform sampling error is taken into account; (3) both errors are considered. In category (1), the round trip signal propagation distance of i channel is calculated by $|S_0P_0R_i|$, and the idea PRF (the dis- tances of the SAR antenna moving in every pulse repetition interval are equal to $L/2m$) adopted. The round trip signal propagation distance of i channel should be calculated by $2|E_iA_i|$ in category (2). In category (3), the signal propagation distance is calculated as category (1), however, the system operating PRF does not equal to ideal PRF.

4.3   Simulation of the mode with multiple azimuth beams and scan in elevation

Neglecting azimuth phase errors, the point target impulse function generated in section 4.2 of the multiple azimuth beams SAR can be expressed by the equivalent single beam SAR's impulse function (Andrea *et al.*, 1996; Jurgen *et al.*, 2002).

$$h_{\text{SAR}}(\tau,t;r_0,\xi) = W_a\left(\frac{v_s(t-\xi)}{r_0}\right)W_r\left(\tau - \frac{2\Delta R((t-\xi);r_0)}{c}\right) \times$$

$$\exp(-j(\frac{4\pi\Delta R((t-\xi);r_0)}{\lambda})) \qquad (9)$$

where τ is fast time in range direction, t is slow time in azimuth direction of the equivalent single beam SAR, and (r_0, ξ) is the point target position. If scan mode is adopted, the response function can be expressed as follows.

$$h_{\text{scan}}(\tau,t;r_0,\xi) = h_{\text{SAR}} \times W_{\text{sc}}(t) \qquad (10)$$

where $W_{\text{sc}}(t)$ is rectangle function corresponding to the subswath illumination time T_D, and can be expressed as follows.

$$W_{\text{sc}}(t) = \sum_k \text{rect}((t - kT_R)/T_D) \qquad (11)$$

Thus, the echo data simulation of the same subswath in MAB-ScanSAR can be realized as following. At first, the multiple beams stripmap mode echo data corresponding to this subswath is generated where the ScanSAR parameters are adopted. Then, the temporal relation of each subswath is used to intercept the corresponding burst data directly. However, if the overlapping and stitching of adjacent subswaths are simulated, the echo data should be generated by adjusting the antenna direction based on the working process of scan mode.

5 DISCUSSION OF IMAGING ALGORITHMS IN MAB-SCANSAR

5.1 Characteristics comparison of three common ScanSAR imaging algorithms

SPECAN, full aperture RD and full aperture CS are common imaging algorithms in ScanSAR. Among them SPECAN is the first choice for low resolution quick look processing of ScanSAR. Since only linear range migration item is corrected in SPECAN, it is not fit for high resolution imaging (refer to simulation analysis in section 6.1). If SPECAN is used in high resolution imaging, the effect of range curvature should be considered. Thus the priority of high computing efficient is lost. Full aperture algorithm is known as coherent multiple bursts algorithm too. It firstly fills zeros to the gaps of the ScanSAR echo data, and then the common stripmap imaging algorithms is used. The biggest merit of this method is that it can be obtained from conventional stripmap imaging processor easily. But the computing efficiency will be degraded to a certain degree because of the zero padding operation. Furthermore, the image quality is degraded because of the cross modulation among azimuth bursts. For amplitude image, this effect can be restrained by a subsequent low passing filter (Cumming et al., 2005).

5.2 Computational analysis of three imaging algorithms

The flowcharts of processing one subswath in MAB-ScanSAR with the algorithms discussed in section 5.1 are displayed in Fig. 4, where the operation of azimuth phase error compensation is to remove the phase errors introduced by multiple azimuth beams. The subswaths stitching are same to

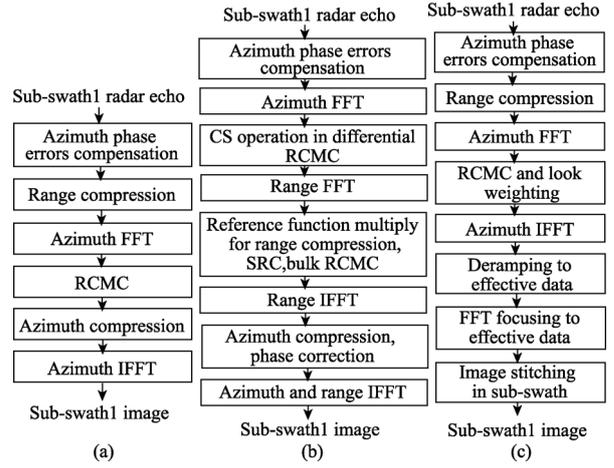

Fig. 4   The flowchart of three imaging algorithms
(a) RD algorithm; (b) CS algorithm; (c) SPECAN algorithm

conventional ScanSAR. For the high resolution in MAB-ScanSAR, the effect of range curvature should be considered (refer to section 6.1). Hence, the flowchart of conventional SPECAN (Sack et al., 1985) changes to Fig. 4(c). Although RD algorithm has a simple structure, the small range migration is also required. However, CS algorithm can get accurate imaging result under the condition of big squint angle and big range migration. So, CS is well used in high resolution imaging.

Using the parameters of section 6.1, the computation comparisons of the preceding three imaging algorithms are listed at below. Since the first steps of phase error compensation are the same, they can be neglected when we compare the computation differences. Assume the number of input range lines are $N_{\text{az}}=65536$, the sampling number of each input range line is $N_{\text{rg}}=16384$, the sampling number of each output range line is $N_{\text{rg\_out}}=15360$, and the interpolation kernel $M_{\text{ker}}=8$, then the total number of floating operations in RD can be approximated by (12) (Cumming et al., 2005).

$$\text{FLOP}_{\text{RD}} = 5N_{\text{rg}}N_{\text{az}}\log_2 N_{\text{rg}} \times 2 + 6N_{\text{rg}}N_{\text{az}} + 6N_{\text{rg\_out}}N_{\text{az}} +$$
$$5N_{\text{rg\_out}}N_{\text{az}}\log_2 N_{\text{az}} \times 2 + 2(2M_{\text{ker}}-1)N_{\text{rg\_out}}N_{\text{az}} =$$
$$354.0664 \text{ (GFLOP)} \qquad (12)$$

The total number of floating operations in CS is

$$\text{FLOP}_{\text{CS}} = 5N_{\text{rg}}N_{\text{az}}\log_2 N_{\text{rg}} \times 3 + 6N_{\text{rg}}N_{\text{az}} \times 2 +$$
$$6N_{\text{rg\_out}}N_{\text{az}} + 5N_{\text{rg\_out}}N_{\text{az}}\log_2 N_{\text{az}} =$$
$$324.9411 \text{ (GFLOP)} \qquad (13)$$

Assume the processing length of each burst is $N_{\text{Burst}}=8192$, even if the floating operations of image stitching and phase errors compensation are neglected, the additional floating operations of SPECAN (Fig. 4(c)) relative to RD still can be expressed as

$$\text{FLOP}_{\text{add}} = 6N_{\text{rg\_out}}N_{\text{Burst}} \times 2 +$$
$$5N_{\text{rg\_out}}N_{\text{Burst}}\log_2 N_{\text{Burst}} \times 2 =$$
$$17.8677 \text{ (GFLOP)} \qquad (14)$$

Preceding comparisons show that CS algorithm has superiority in MAB-ScanSAR on computation too. Certainly, the choice of specific algorithm should give an integrated consideration of the already existing imaging processors and the computing complexity etc.

6 SIMULATION ANALYSIS

Nowadays, almost all radar satellites have yaw steering which can reduce azimuth phase errors effectively and simplify the signal processing. So yaw steering is added to all the simulations in the paper. Other main parameters are listed in Table 1.

Table 1 Simulation parameters

Satellite height/km	800	Ideal PRF/Hz	1656
Orbit inclination angle/°	98.6	Subswath1 PRF /Hz	1680
Antenna length/m	9	Subswath2 PRF /Hz	1665
Wavelength/m	0.05656	Subswath3 PRF /Hz	1680
Bandwidth/MHz	33	Subswath4 PRF /Hz	1665
Sampling frequency /MHz	40	Subswath5 PRF /Hz	1680
Pulse duration /μs	20		

6.1 Simulation analysis of high resolution SPECAN

To ensure the imaging quality, whether to correct the range curvature should be analyzed when SPECAN is used to form high resolution image. As an example, if parameters in Table 1 are used to analyze the first subswath. The range curvature in MAB-ScanSAR can be approximated by Eq. (15) (Curlander *et al.*, 1991). The range curvature is 152.5 m (about 5.5 gates) even in a burst when the satellite is over the equator and the look angle is 30°. Thus, the effect of range curvature can not be ignored already.

$$R_{\text{square}} = \frac{\lambda |f_{\text{d}r}|}{4}(t - t_0)^2 \approx \frac{\lambda |f_{\text{d}r}|}{4}(\frac{\lambda \cdot R_c}{2Dv_s})^2 \tag{15}$$

where t_0 is the time when the center of the radar beam crosses the target, R_c is the beam length, D is the equivalent antenna length, v_s is the satellite velocity. The imaging results of a burst formed by SPECAN are displayed in Fig.5 where the differential path error is removed. Fig.5(a)(b) are imaging results when the range curvature is included in range migration correction (RCMC). The azimuth 3dB resolution is 4.5 m and the slant
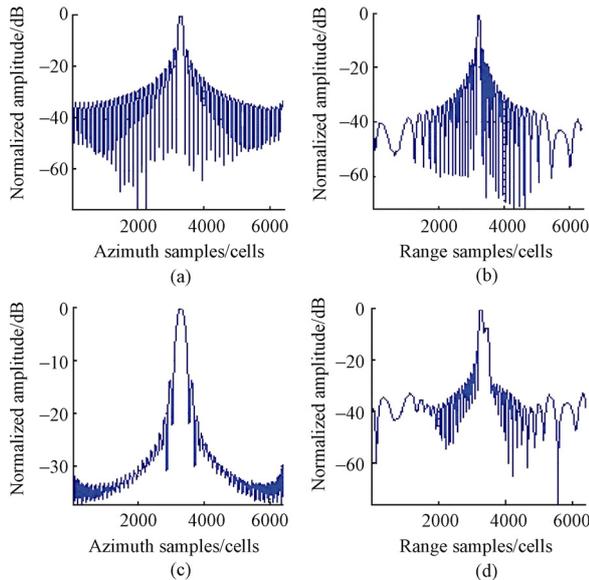

Fig. 5 SPECAN imaging results
(a) Azimuth profile map with accurate RCMC; (b) Range profile map with accurate RCMC; (c) Azimuth profile map when the range curvature is ignored; (d) Range profile map when the range curvature is ignored

range 3 dB resolution is 4.6 m. So, the point target is focused

well. If the range curvature is neglected, the decoupling in range and azimuth direction can not be achieved and the point target can not be focused. The profile maps along azimuth and range direction are displayed in Fig.5(c)(d), where the azimuth 3 dB resolution changes to 9.3 m, the slant range 3 dB resolution changes to 6.3 m and the left sidelobe is higher than −7.5 dB. Hence, simulation results prove that range curvature must be considered in RCMC when the parameters in Table 1 are used. Thus, the superiority of SPECAN relative to full aperture RD or CS does not exist now.

Since the abscissas are interpolated 64 times in Fig. 5, the range sampling spacing is 4.55/64=0.07 m and azimuth sampling spacing of SPECAN can be determined by Eq. (16) (Cumming *et al.*, 2005).

$$\delta_a = \frac{v_s \times PRF_e}{64 \cdot N_{\text{fft}}/|f_{\text{d}r}|} \tag{16}$$

where v_s is the velocity of satellite, PRF_e is the equivalent PRF, N_{fft} is the FFT length of the focusing operation in SPECAN, $f_{\text{d}r}$ is the Doppler rate. In the instance, v_s is 7451.8 m/s, PRF_e is 10080 Hz, N_{fft} is 16384 points, $|f_{\text{d}r}|$ is 1890.9 Hz/s, so the azimuth sampling interval is 0.04 m. The normalized amplitude coordinates is calculated by 20log (f/f_{max}) in the paper, where f_{max} is the maximum amplitude, f is real amplitude of the samples.

6.2 Simulation analysis of phase errors caused by multiple azimuth beams

The process of MAB-ScanSAR is same to ScanSAR, if the azimuth phase errors are compensated well or the effects of these phase errors can be ignored. Different azimuth phase errors are generated by the methods of section 4.2 and the imaging analysis is done by CS algorithm. To avoid cross modulation among the bursts, the imaging operation is only applied on the effective burst when the point target is analyzed. Because of yaw steering, the effect of nonuniform sampling error becomes marginal and the variation is small along the orbit. For example, when the parameters of Table 1 and the data of first subswath are used, the maximum false target amplitude is only about −42.5 dB (Fig.6(c)) even if the system operating PRF deviates from ideal PRF (1656 Hz) 200 Hz (corresponding PRF_e is 11136 Hz). Thus, the effect of this error on imaging quality can be ignored at all.

The effect of differential path error is changed greatly along the orbit because of the Earth rotation. Simulation results are displayed in Fig.6 when the satellite at 35°N where the effect of differential path error becomes serious.

The azimuth profile map with combined phase errors is displayed in Fig.6(a) and the maximum amplitude of the false target becomes −9 dB. The false targets are removed effectively by Eq. (6), SNR has also been greatly improved and the result is plotted in Fig.6(b). The imaging result only with nonuniform sampling error is displayed in Fig.6(c). The comparision between Fig.6(b) and Fig.6(c) shows that the residual false targets in Fig.6(b) are mainly caused by nonuniform sampling error and the effect to imaging quality can be neglected. For the convenience of analysis the imaging results without both phase errors is displayed in Fig. 6(d). The sampling spacing of the abscissas is v_s/PRF_e=0.67m in Fig. 6.
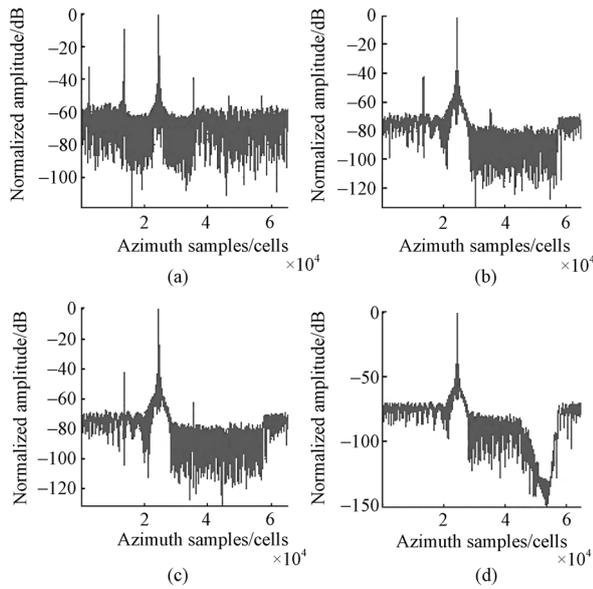

Fig. 6   Simulation analysis of phase errors at 35°N
(a) With both phase errors; (b) Compensated differential path error of (a);
(c) Only with nonuniform sampling error; (d) Without phase errors

6.3   Comparative analysis of imaging results in MAB-ScanSAR

The point target image results of stripmap mode, ScanSAR mode and MAB-ScanSAR (after compensating differential path error) are presented in Fig.7, where the look angle is 30°, system operating PRF is 1680 Hz, and the satellite is over the equator. Furthermore, the scan mode is single look and five subswaths.

The horizontal direction is the azimuth direction in Fig.7. For convenience of comparison the azimuth sampling spacing is unified to v_s/PRF=4.44 m, and the sampling spacing in range direction is 4.55 m. The quantitative indexes of the preceding imaging results are summarized in Table 2.

Table 2   Imaging performance comparison of different modes

Work mode	ρ_r/m	ρ_a/m	Overall swath width/km
Stripmap mode	4.6	4.5	69.2
Scan mode	4.6	27	346
MAB-ScanSAR	4.6	4.5	346

In Table 2, ρ_r is slant range 3 dB resolution, ρ_a is azimuth

Fig. 7   Grayscale images of point target for three work mode
(a) Stripmap mode; (b) Scan mode; (c) MAB-ScanSAR mode

3dB resolution. The overall swath width denotes the optimal width when the overlap between the subswaths is neglected. Considering the subswath overlaps and the subswath stitching in real system, the real overall swath width is less than preceding value (Jurgen *et al.*, 2002; Cumming *et al.*, 2005). The simulation results show that MAB-ScanSAR can extend the swath width 5 times and keep the azimuth resolution same as stripmap mode under ideal condition.

7   CONCLUSIONS

To achieve wider swath width and keep the high azimuth resolution unchanged, a new work mode MAB-ScanSAR is proposed in the paper. The optimal theory performance is given. Based on the analysis of the main phase errors, the specific compensation methods are presented and several imaging algorithms suitable for this mode are studied too. The effectiveness and feasibility of the proposed methods are proved by the point target simulation.
